

New jigsaw piece for the repair of DNA crosslinks

May 27 2014

Chromosomenanalyse nach Behandlung der Zellen mit Mitomycin C (MMC), ein DNA-Crosslink-induzierendes Chemotherapeutikum

Crosslink-inducing agents used in chemotherapy.

Environmental influences such as ionizing radiation, intense heat or various chemical substances damage the DNA constantly. Only thanks to efficient repair systems can mutations – changes in the DNA – largely be prevented. DNA crosslinks that covalently link both strands of the DNA double helix are among the most dangerous DNA lesions. Crosslinks block DNA replication and can thus cause cell death. Moreover, their faulty repair can trigger the development of tumors. Crosslink repair is highly complex and only vaguely understood today.

A team of cancer researchers headed by Alessandro Sartori from the University of Zurich now reveals interesting details as to how cells recognize crosslink [damage](#). In their study recently published in *Cell Reports*, the scientists demonstrate that the interplay between two

specific proteins is crucial for the flawless repair of crosslink damage.

Repair protein recognizes crosslink damage with the aid of a signal protein

For their study, the researchers examined the Fanconi [anemia](#) signal pathway, which coordinates the complex repair of crosslinks, with the aid of genetically modified and unchanged cells. Sartori and his team wanted to find out whether and how the signal pathway and the repair protein CtIP interact with one another. "We are able to show that CtIP recognizes and repairs crosslinks efficiently with the aid of the Fanconi anemia [signal pathway](#), or FANCD2 to be more precise," explains Sartori. The scientists also discovered the point where CtIP attaches itself to the FANCD2 protein. According to the researchers, the interplay between the two proteins is necessary for the flawless and smooth repair of crosslink damage as it prevents the relocation of entire chromosome sections to another position (see figure). Referred to as chromosomal translocation, the process is one of the main causes of the development of cancer.

These days, substances that specifically trigger crosslink damage are used in cancer chemotherapy. The new findings are therefore important for both our understanding of the development of cancer and the further development of improved drugs.

Fanconi anemia

Fanconi anemia (FA) is a rare congenital disorder that was first described in 1927 by Guido Fanconi (1892–1979), Professor of Pediatrics at the University of Zurich. Fanconi anemia is triggered by mutations in genes that regulate the repair of DNA crosslinks. Patients who suffer from Fanconi anemia display [bone marrow failure](#) already

during childhood and have a risk of developing cancer that is about 1,000 times higher compared to healthy individuals. Only around a third of Fanconi anemia patients live beyond the age of 30.
