

A sweet bacterium keeps track of time

November 18 2014

Caulobacter crescentus's cellular division produces different daughter cells, some with capsules (black cells) and some without (red cells). Credit:

Researchers are studying the *Caulobacter crescentus* bacterium because of its developmental process and cellular cycle, which serve as models for a number of pathogenic bacteria. They all have in common the use of polysaccharides to create a particularly effective protective envelope, or capsule. Professor Viollier's laboratory at the University of Geneva's (UNIGE) Faculty of Medicine has just unraveled the secrets of capsule formation during the cellular cycle and perhaps even identified potential Achilles' heel of bacteria. These results were published in the last edition

of the eLife journal.

Silvia Ardisson, researcher in the Department of Microbiology and Molecular Medicine at UNIGE's Faculty of Medicine, works with *Caulobacter crescentus*, a bacterium that shows a particularly interesting cell division. In fact, as with eukaryotic organisms, division of *Caulobacter* cells generates two different daughter cells, which can be easily separated. Researchers take advantage of this feature to obtain populations of synchronized bacteria that can be used to study specific cell cycle processes.

The sugar capsule, typical of pathogens

Like other bacteria, including several pathogenic species, *Caulobacter crescentus* presents a capsular envelope made of polysaccharides (sugars). This envelope protects [bacteria](#) from viruses, as well as from the human immune system. Professor Patrick Viollier's team studies how cells produce the capsule at the right time and just identified some of the underlying regulatory mechanisms.

One of the daughter cells lacks the capsule

Of the two different daughter cells generated by *Caulobacter* at each [cell division](#) only one is equipped with the capsule. This is what scientists noticed, and now they can now explain the reasons behind such a difference. In fact, the researchers showed that the synthesis of the capsule is controlled by the same mechanisms that regulate the cell cycle, and identified the protein that inhibits the production of the sugar capsule in one of the [daughter cells](#).

"An uncharted path seems to have opened for the development of a new kind of antibiotics, products that would imitate the action of this

inhibitory protein," comments Silvia Ardisson, who also imagines a type of medicine that "would strip the pathogens," and therefore disarm an entire bacteriological spectrum.
