In the hunt for better knowledge on the aging process, researchers from Lund University have now enlisted the help of small birds. A new study investigates various factors which affect whether chicks are born with long or short chromosome ends, called telomeres.

The genetic make-up of our cells consists of genes lined up on chromosomes. The ends of the chromosomes are called telomeres, and they protect the chromosomes from sticking to each other. The longer the telomeres, the longer time the chromosomes are able to function. And conversely, the shorter these ends, the less time left for the [chromosomes](#), and thereby also for the cells to function properly. More knowledge of telomeres can therefore be valuable in understanding the aging process in humans and other animals.

In the present study, researchers from Lund University looked for explanations for the large variation in telomere length in newborn individuals. This begs the question, because it should be advantageous to start life with longer telomeres rather than [shorter telomeres](#).

"It is remarkable that already so early on in life, there are already such major differences between individuals, both in humans and in animals", says Asghar Muhammad, one of the researchers behind the study.

The researchers used data from a 30-year-long study of individually recognizable ringed great reed warblers at lake Kvismaren, south Central Sweden. The aim of the study was to find out which inheritance factors affect the length of the [chromosome ends](#) in chicks. Thanks to the long series of measurements, it was possible to compare the length of telomeres in newborn individuals with that of their parents when these were newly hatched chicks.

The results showed that the length of the telomeres in this songbird depends on a fairly even distribution of hereditary and non-hereditary

factors. It appears that the older the female is at the time of the chicks' birth, the longer the chicks' chromosome ends will be. The non-hereditary factors consist of various aspects connected specifically to the female, not to the male. For example, the female can affect the hormone levels or antibodies in the egg yolk which the chick ingests even before hatching. These factors may then affect how fast telomeres shorten until [chicks](#) are 10 days old.

Asghar Muhammad observes that the great reed warblers differ from humans in this, as previous research has shown that the non-hereditary factors which are significant to chromosome ends in human offspring are connected to the father rather than the mother.

"In humans, there is a link between the father's age and the length of the child's telomeres. The older the father, the longer the [telomeres](#)" says Asghar Muhammad.
