

# Study pinpoints genes that make plant stem cells, revealing origin of beefsteak tomatoes

May 25 2015

Scientists have identified a set of genes that control stem cell production in

tomato, the key to fruit size and explaining the origin of giant fruits like the beefsteak. These images show the impact of specific gene mutations on plant architecture and flower formation (top row); fruit size (middle row), and the size of the plant's growing tip, called the meristem (bottom row). The left column (top to bottom), shows a wild-type tomato plant. Compare this with two mutants: one, called fab (middle column), the other called fin (right column). Top row: While the wild-type plant has no branches on the stem that supports flowers, the two mutants show branching -- called fasciation -- and the flowers have extra petals [insets]. Middle row: the wild fruit has 2 compartments, called locules [white arrows], bearing a jelly-like substance and seeds; the mutants have additional locules. Bottom row: the meristems of the two mutants are larger than that of the the wild plant, indicating that they contain more stem cells. Credit: Lippman Lab, CSHL

A team of scientists at Cold Spring Harbor Laboratory (CSHL) has identified a set of genes that control stem cell production in tomato. Mutations in these genes explain the origin of mammoth beefsteak tomatoes. More important, the research suggests how breeders can fine-tune fruit size in potentially any fruit-bearing crop. The research appears online today in *Nature Genetics*.

In its original, wild form the tomato plant produces tiny, berry-sized fruits. Yet among the first tomatoes brought to Europe from Mexico by conquistador Hernan Cortez in the early 16th century were the huge beefsteaks. Producing fruits that often weigh in at over a pound, this variety has long been understood to be a freak of nature, but only now do we know how it came to be.

The secret of the beefsteak tomato, CSHL Associate Professor Zachary Lippman and colleagues show, has to do with the number of stem cells in the plant's growing tip, called the meristem. Specifically, the team traced an abnormal proliferation of stem cells to a naturally occurring mutation

that arose hundreds of years ago in a gene called CLAVATA3. Selection for this rare mutant by plant cultivators is the reason we have beefsteak tomatoes today.

In plants, like animals, stem cells give rise to the diversity of specialized cell types that comprise all tissues and organs. But too many stem cells can be a problem. In people, too many stem cells can lead to cancer. Similarly, when stem [cell production](#) goes unchecked in plants, growth becomes imbalanced and irregular, threatening survival.

The finely tuned balance of stem cell production in plants is controlled by genes that have opposite activities. Specifically, a gene known as WUSCHEL promotes stem cell formation, whereas CLAVATA genes inhibit stem cell production. Several genes in the CLAVATA family encode for receptor proteins that sit on the surface of plant cells—the equivalent of locks—as well as a series of proteins that dock at these receptors—the equivalent of keys. When a CLAVATA key is made and fits in a CLAVATA lock, a signal is sent inside the cell that tells WUSCHEL to slow down. Critically, this prevents WUSCHEL from making too many stem cells.

Giant beefsteak tomatoes were first brought to Europe by the conquistador Cortez in the early 1500s. Here, a hand-colored woodblock illustration from the 1590 German language edition of Mattioli's Commentaries on Dioscorides edited by Joachim Camerarius of Frankfurt (Mattioli 1590). It is therefore no surprise that when CLAVATA genes are mutated, the plant makes too many stem cells in the meristem. However, in the newly reported experiments, Lippman's team examined never before studied mutant tomato plants, three of which contained faulty genes encoding enzymes that add sugar molecules to proteins. How was this discovery relevant to plant stem cells? Lippman's experiments revealed that the enzymes, called arabinosyltransferases (ATs), add sugar molecules called arabinoses to CLAVATA3—one of the CLAVATA keys. Remarkably, these sugars are required for the key to fit a CLAVATA lock.

The team's important discovery: changing the number of sugars attached to the CLAVATA3 key can change the number of stem cells. Three sugars is normal, and produces normal growth. But when the one or more sugars on the CLAVATA3 key are missing, the key no longer fits properly in the lock. WUSCHEL therefore sends its signal to make new stem cells, but that message is not accompanied by a "stop" signal. There is abnormal growth; the plant's fruit becomes extremely large. Revisiting the original beefsteak tomato variety, Lippman and collaborator Esther van der Knaap at Ohio State University found that the secret of the beefsteak is that not enough of the CLAVATA3 key is made in the meristem. The result is too many [stem cells](#) and giant fruits.

The research more broadly shows that there is a continuum of growth possibilities in the [tomato plant](#), and in other plants—since the CLAVATA pathway is highly conserved in evolution and exists in all plants. By adjusting the number of sugars on CLAVATA keys, and through other mutations affecting components of the pathway, Lippman and colleagues show it is possible to fine-tune growth in ways that could allow breeders to customize fruit size.
