

# How strong is gravity on other planets?

January 1 2016, by Matt Williams

---

Gravity is a fundamental force of physics, one which we Earthlings tend to take for granted. You can't really blame us. Having evolved over the course of billions of years in Earth's environment, we are used to living with the pull of a steady 1 g (or  $9.8 \text{ m/s}^2$ ). However, for those who have gone into space or set foot on the Moon, gravity is a very tenuous and precious thing.

Basically, [gravity](#) is dependent on mass, where all things – from stars, [planets](#), and galaxies to light and sub-atomic particles – are attracted to one another. Depending on the size, mass and [density](#) of the object, the gravitational force it exerts varies. And when it comes to the planets of our [solar system](#), which vary in size and mass, the strength of gravity on their surfaces varies considerably.

For example, Earth's gravity, as already noted, is equivalent to  $9.80665 \text{ m/s}^2$  (or  $32.174 \text{ ft/s}^2$ ). This means that an object, if held above the ground and let go, will accelerate towards the surface at a speed of about 9.8 meters for every second of free fall. This is the standard for measuring gravity on other planets, which is also expressed as a single g.

In accordance with Isaac Newton's law of universal gravitation, the gravitational attraction between two bodies can be expressed mathematically as  $F = G (m^1 m^2 / r^2)$  – where F is the force,  $m^1$  and  $m^2$  are the masses of the objects interacting, r is the distance between the centers of the masses and G is the gravitational constant ( $6.674 \times 10^{-11} \text{ N m}^2/\text{kg}^2$ ).

Based on their sizes and masses, the gravity on another planet is often expressed in terms of g units as well as in terms of the rate of free-fall acceleration. So how exactly do the planets of our solar system stack up in terms of their gravity compared to Earth? Like this:

## Gravity on Mercury:

With a mean radius of about 2,440 km and a mass of  $3.30 \times 10^{23} \text{ kg}$ , Mercury is approximately 0.383 times the size of Earth and only 0.055 as massive. This makes Mercury the smallest and least [massive planet](#) in the solar system. However, thanks to its high density – a robust  $5.427 \text{ g/cm}^3$ , which is just slightly lower than Earth's  $5.514 \text{ g/cm}^3$  – Mercury has a [surface gravity](#) of  $3.7 \text{ m/s}^2$ , which is the equivalent of 0.38 g.

## **Gravity on Venus:**

Venus is similar to Earth in many ways, which is why it is often referred to as "Earth's twin". With a mean radius of  $4.6023 \times 10^8 \text{ km}^2$ , a mass of  $4.8675 \times 10^{24} \text{ kg}$ , and a density of  $5.243 \text{ g/cm}^3$ , Venus is equivalent in size to 0.9499 Earths, 0.815 times as massive, and roughly 0.95 times as dense. Hence, it is no surprise why the gravity on Venus is very close to that of Earth's –  $8.87 \text{ m/s}^2$ , or 0.904 g.

## **Gravity on the Moon:**

This is one astronomical body where human beings have been able to test out the affects of diminished gravity in person. Calculations based on its mean radius (1737 km), mass ( $7.3477 \times 10^{22} \text{ kg}$ ), and density ( $3.3464 \text{ g/cm}^3$ ), and the missions conducted by the Apollo astronauts, the surface gravity on the Moon has been measured to be  $1.62 \text{ m/s}^2$ , or 0.1654 g.

## **Gravity on Mars:**

Mars is also similar to Earth in many key respects. However, when it comes to size, mass and density, Mars is comparatively small. In fact, its mean radius of 3.389 km is the equivalent of roughly 0.53 Earths, while its mass ( $6.4171 \times 10^{23} \text{ kg}$ ) is just 0.107 Earths. Its density, meanwhile, is about 0.71 of Earths, coming in at a relatively modest  $3.93 \text{ g/cm}^3$ . Because of this, Mars has 0.38 times the gravity of Earth, which works out to  $3.711 \text{ m/s}^2$ .

## **Gravity on Jupiter:**

Jupiter is the largest and most massive planet in the solar system. Its mean radius, at  $69,911 \pm 6 \text{ km}$ , makes it 10.97 the times the size of Earth, while its mass ( $1.8986 \times 10^{27} \text{ kg}$ ) is the equivalent of 317.8 Earths.

But being a gas giant, Jupiter is naturally less dense than Earth and other terrestrial planets, with a mean density of  $1.326 \text{ g/cm}^3$ .

What's more, being a gas giant, Jupiter does not have a true surface. If one were to stand on it, they would simply sink until they eventually arrived at its (theorized) solid core. As a result, Jupiter's surface gravity (which is defined as the force of gravity at its cloud tops), is  $24.79 \text{ m/s}$ , or  $2.528 \text{ g}$ .

## Gravity on Saturn:

Like Jupiter, Saturn is a huge gas giant that is significantly larger and more massive than Earth, but far less dense. In short, its mean radius is  $58232 \pm 6$  km (9.13 Earths), its mass is  $5.6846 \times 10^{26}$  kg (95.15 times as massive), and has a density of  $0.687 \text{ g/cm}^3$ . As a result, its surface gravity (again, measured from the top of its clouds) is just slightly more than Earth's, which is  $10.44 \text{ m/s}^2$  (or 1.065 g).

## Gravity on Uranus:

With a mean radius of 25,360 km and a mass of  $8.68 \times 10^{25}$  kg, Uranus is approximately 4 times the size of Earth and 14.536 times as massive. However, as a gas giant, its density ( $1.27 \text{ g/cm}^3$ ) is significantly lower than Earth's. Hence, why its surface gravity (measured from its cloud tops) is slightly weaker than Earth's –  $8.69 \text{ m/s}^2$ , or 0.886 g.

## Gravity on Neptune:

With a mean radius of  $24,622 \pm 19$  km and a [mass](#) of  $1.0243 \times 10^{26}$  kg, Neptune is the fourth largest planet in the solar system. All told, it is 3.86 times the size of Earth and 17 times as massive. But, being a [gas giant](#), it has a low density of  $1.638 \text{ g/cm}^3$ . All of this works out to a surface gravity of  $11.15 \text{ m/s}^2$  (or 1.14 g), which again is measured at Neptune's [cloud tops](#).

All in all, gravity runs the gamut here in the solar system, ranging from 0.38 g on Mercury and Mars to a powerful 2.528 g atop Jupiter's clouds. And on the Moon, where astronauts have ventured, it is a very mild 0.1654 g, which allowed for some fun experiments in near-weightlessness!

Understanding the effect of zero-gravity on the human body has been essential to space travel, especially where long-duration missions in orbit and to the International Space Station have been concerned. In the coming decades, knowing how to simulate it will come in handy when we start sending astronauts on deep space missions.

And of course, knowing just how strong it is on other planets will be essential to manned missions (and perhaps even settlement) there. Given that humanity evolved in a 1 g environment, knowing how we will fare on planets that have only a fraction of the gravity could mean the difference between life and death.
