

Creating a molecular snapshot of the way proteins interact could help development of new cancer drugs

August 22 2016, by Amy Adams

When new cancer cells break free of their original tumor, they travel the blood system and land in distant organs to kindle new tumors. It's these new cancer settlements, through a process called metastasis, that are often deadly.

One approach to preventing that spread has involved blocking the interaction of two proteins: one called Gas6 in the bloodstream and another called Axl that bristles along the outside of [cancer cells](#). When these two interact, it signals the cell to pack up and go.

Despite the promise, attempts at blocking that interaction haven't worked.

Jennifer Cochran, an associate professor of bioengineering, and Amato Giaccia, a professor of radiation oncology, thought they might try an alternate approach. Their idea was to create a decoy Axl [protein](#) that would latch onto Gas6 in the bloodstream, sopping up all the available Gas6 and preventing any from being available to bind to the real Axl.

To create that drug, the duo made more than 10 million mutations to the Axl protein, then tested those variants to find one that stuck most tightly to Gas6. One in particular stood out. It latched on to Gas6 much more tightly than the normal protein.

In mice, this Axl decoy protein when injected into the bloodstream

sequesters the Gas6 and prevents metastasis in both breast and ovarian cancers. The team is now working to translate that success to people.

An additional question for Cochran was what changed in their mutated protein to make it so effective. "We wanted to understand the interaction on a deeper level," she said. "That curiosity is part of being an engineer."

Satisfying that curiosity could also help the team understand how the two proteins interact and predict ways of mutating other proteins to create

drugs. "The idea is that if you could study this interaction you could use it in a predictive way down the road," she said.

Working with Irimpan Mathews, a structural biology scientist at SLAC's Stanford Synchrotron Radiation Lightsource, Cochran and her team formed crystals of the mutant Axl interacting with Gas6. They then used a technique called X-ray crystallography, which essentially creates a molecular portrait of the proteins and their interactions.

"The crystallography revealed unique features that couldn't have been predicted," says Cochran, who is also a member of Stanford Bio-X. The tightest binding variant of Axl had a little pocket that helped it bind even tighter to the Gas6.

The Stanford-SLAC collaborators are now using similar methods to interfere with two proteins that help blood vessels infiltrate and support tumors, supported by a Stanford ChEM-H program to encourage Stanford faculty collaborations with SLAC.
