Breast cancer researchers from the Florida campus of The Scripps Research Institute (TSRI) have developed a novel approach for identifying how chemicals in the environment—called environmental estrogens—can produce infertility, abnormal reproductive development, including "precocious puberty," and promote breast cancer.

Environmental estrogens work by binding to the [estrogen receptor](#), a protein in cells that guides sexual maturation and reproduction. The new research shows how high-resolution imaging techniques could give scientists a window into how exposure to these chemicals may impact public health.

This research method could also be used to speed up the discovery of new drugs for [breast cancer](#) and many other diseases, added study senior author Kendall Nettles, associate professor at TSRI.

The study was published online ahead of print in the journal *Cell Chemical Biology*.

Taking Snapshots of a Crucial Receptor

Environmental estrogens control the estrogen receptor's activity by changing its shape, which can mimic the effects of estrogen. These chemicals can also block receptor activity, as seen with the breast cancer therapy tamoxifen.

These changes are often exceedingly small, in the sub-ångström range (one ångström is equal to one ten-billionth of a meter). In fact, changes to even a single atom in a chemical or endocrine therapy drug can often drive widely divergent outcomes, but the resolution of the typical crystal structure does not allow visualization of these small changes.

Nettles calls the approach in the new study "super-resolution x-ray crystallography."

X-ray crystallography is a technique that produces a snapshot of the receptor's 3-D atomic structure. Like the images produced by photography or microscopy, x-ray crystal structures have a certain resolution, or level of detail, that can be visualized. With optical

microscopy, super-resolution imaging—a discovery for which researchers were awarded the Nobel Prize in 2014—can be achieved by combining many images to produce a sharper picture.

Nettles and his colleagues reasoned that they could use a similar approach with x-ray crystallography to compare molecular snapshots, or structures, and better understand how estrogenic chemicals control [receptor activity](#).

Developing a Framework for Drug Design

They found that by combining data about structural disturbances from many structures with activity profiles of their ligands (the estrogenic chemicals), researchers can identify the sub-ångström details that determine endocrine disruption.

"Our novel approach offers a framework for understanding the diverse effects of environmental estrogens and other endocrine disruptors, furthering efforts to develop improved breast cancer therapies," said TSRI Research Associate Jerome C. Nwachukwu, first author of the study. "This approach can also be applied to other allosteric receptors."

Super-resolution [x-ray crystallography](#) can also be applied to the large groups of receptors that comprise the targets for most known drugs. With structure-based drug design, chemists can use this new approach to visualize how to modify drug-candidate chemicals to promote the desirable therapeutic profile.
