Nonresident seabirds in Central California concentrate their foraging along the continental shelf break, according to a study published January 25, 2017 in the open-access journal *PLOS ONE* by Anna Studwell who has worked jointly with colleagues at Point Blue Conservation Science, the SFSU Department of Geography & Environment, and the Romberg

Tiburon Center, USA.

Seabird aggregations in the ocean are associated with concentrations of prey, and so have been used to identify and designate [marine protected areas](#) worldwide. Central California is a highly-used foraging area for seabirds, and most species that breed locally are constrained to islands near the coast. To identify high-use foraging sites for nonresident seabirds—those that do not breed locally—Studwell and colleagues used a 10-year dataset that included seabird counts and oceanographic information. The researchers focused on six nonresident seabird species: *Phoebastria nigripes* (black-footed albatross), *Ardenna griseus* (sooty shearwater), *Ardenna creatopus* (pink-footed shearwater), *Fulmarus glacialis* (northern fulmar), *Phalaropus lobatus* (red-necked phalarope) and *Phalaropus fulicarius* (red phalarope).

The researchers found that for nonresident seabirds, the highest use foraging area, and a site of high conservation priority when considering the species' IUCN Red List status, is along the continental shelf break, particularly near Cordell Bank. The lack of protected offshore areas has been called the "missing dimension in ocean conservation," say the researchers, and this work provides a way to prioritize areas that are high use for multiple seabird species. Notably, combining resident and nonresident seabird [foraging](#) areas could help identify critical marine [areas](#) and further inform conservation efforts.
