An international team of scientists has organized the available

bibliographic data on bilayer graphene, a high-potential material with possible applications in electronics and optics. The review paper was published in *Physics Reports*.

## **The graphene rush**

The development of microelectronics is closely associated with a search for new technology and materials for use in transistors. A promising material, graphene, gripped the attention of scientists and engineers alike thanks to its unusual mechanical, electrical, and optical properties. The graphene rush started in 2004 with the publication of a [paper](#) by Konstantin Novoselov and Andre Geim in *Science*. As of today, over 10,000 papers dealing with graphene have been published and more than a thousand patents relating to the material have been granted.

Bilayer graphene, or bigraphene, is one of the exciting forms of graphene, which is currently gaining traction: In 2014 and 2015 alone, more than 1,000 papers about bigraphene were published.

Dr. Alexander Rozhkov, a coauthor of the current review, sums up the team's achievement: "To write the review on bilayer graphene, we spent two years studying and organizing all of the most significant experimental and theoretical findings in the field. As a result, we published a review citing roughly 450 scientific papers on bilayer graphene and related subjects. Right now, it is the most comprehensive review dealing with the issue, both in terms of the sheer number of references and the scope of subject matter."

## **Why two is better than one**

One of the attractive features of graphene is its high charge carrier mobility. In fact, it is dozens of times higher than the analogous quantity

in silicon, the go-to material of modern-day microelectronics. Electrons and holes (electron vacancies) in graphene can move easily and quickly under the influence of an external electric field. However, a transistor based on single-layer graphene has a significant drawback in that it cannot be effectively switched off. This is explained by the fact that graphene does not have a bandgap, i.e., a range of energy values forbidden to its electrons. Consequently, the flow of current through such a transistor cannot be shut down completely.

The main advantage of bilayer graphene is the possibility to locally induce a bandgap and tune its magnitude by applying a strong [electric field](#) perpendicular to the carbon sheets. This means that it could be used to design next-generation transistors that would work faster and use less energy, which is especially important for portable battery-powered devices. In addition, the possibility of bandgap tuning means there is even more potential for applications in optoelectronics and sensors.

Nevertheless, a genuine microelectronics revolution has yet to come. Compared to ordinary graphene, a high-grade bilayer sample is more difficult to manufacture, since one has to control material quality and the precision of layer alignment to preserve high charge mobility and other characteristics.

There are three main types of bigraphene. In *AA*-stacked bilayer graphene, the layers are aligned in such a manner that each atom in the upper sheet sits exactly on top of an atom in the lower sheet. In *AB*-stacked bilayer graphene, the layers are overlaid in a different way, viz.,

only half of the atoms in the upper sheet lie over an atom, while the other half lie over the center of a hexagon in the crystal lattice of the lower sheet (see Fig. 1). In another variation, called *twisted* bilayer graphene, one layer is rotated by a predetermined angle relative the other layer. Each one of the three types has its own peculiar features, which need to be studied.

## Graphene future

By now, many of the initially proposed theoretical schemes and concepts have been absorbed by the scientific community. Predictions made back in the pre-graphene era (the 1980s and '90s) and shortly after the beginning of the graphene rush have been tested thanks to the rapid advances made by experimental graphene science in the last decade. At the present moment, scientists are committed to finding applications for the material. Still, fundamental researchers (not seeking any immediate applications) are also busy solving new problems arising in the field of graphene systems. For one thing, the extent to which the Coulomb repulsion between electrons can affect the properties of graphene systems remains unknown. To tackle this question, concepts relatively new to solid-state physics are discussed, e.g., the marginal Fermi liquid and topologically ordered states.

The authors of the review paper have been studying bilayer graphene for six years. They contributed to the understanding of this material's electronic structure. In particular, they examined the possibility of spontaneous symmetry breaking in *AA*-stacked bilayer graphene. The researchers also theoretically predicted the instability of the electron subsystem in *AA*-stacked bilayer graphene and identified the possibility of antiferromagnetic ordering and spatially inhomogeneous states in a bilayer system. Apart from that, the authors investigated single-electron states in *twisted* bilayer graphene at various twist angles and for various superlattice cell sizes, where the notion of a superlattice cell (aka moiré

pattern cell; see Fig. 2) refers to a relatively large periodically occurring structure in the atomic pattern, which arises when two overlaid graphene sheets are twisted relative to each other.

Dr. Artem Sboychakov, a coauthor of the review and a senior research scientist at the Laboratory No. 1 of the Institute for Theoretical and Applied Electrodynamics commented on the publication of the review: "It is a common feature of all systems with a moiré pattern including twisted [bilayer graphene](#) that they are endowed with rather complex physics—mostly due to the intricacy of their structure. Certain aspects of their behavior such as the effects of the interactions between electrons are not yet fully understood. We should be expecting a number of exciting discoveries in this field."

MIPT's Dr. Alexander Rakhmanov who heads Laboratory No. 1 at the Institute for Theoretical and Applied Electrodynamics added: "Our team has considerable experience in the theoretical studies of electron-electron interactions in graphene-based systems. These days, besides purely analytical approaches, the role of numerical techniques cannot be overestimated. They help us find the answers to many of the important theoretical questions. The authors of this review are primarily doing research at the RIKEN Institute of Physical and Chemical Research in Japan and at the Institute for Theoretical and Applied Electrodynamics, which collaborates closely with MIPT's Department of Electrodynamics of Complex Systems and Nanophotonics. Between these two key institutes, we have enough computing power to conduct extensive computational studies. I think I could sum up the results of my own research and the experience we gained while writing the review by saying that we could expect graphene and systems based on this material to remain a source of scientific inspiration for many researchers—both theorists and experimentalists—for years to come."
