

Scientists discover gene that influences grain yield

April 19 2017

“Field of *Setaria viridis* growing in western Nebraska. In the current issue of *Nature Plants* Huang and colleagues use *Setaria viridis* to identify the inflorescence mutant, sparse panicle 1. A mutation in the maize ortholog conditions a very similar panicle defect, demonstrating the utility of *S. viridis* for gene discovery in the panicoids.” Credit: Donald Danforth Plant Science Center

Researchers at the Enterprise Rent-A-Car Institute for Renewable Fuels at the Donald Danforth Plant Science Center have discovered a gene that influences grain yield in grasses related to food crops. Four mutations were identified that could impact candidate crops for producing renewable and sustainable fuels.

In a paper published April 18, 2017, in *Nature Plants*, a team led by Thomas Brutnell, Ph.D. Director of the Enterprise Institute for Renewable Fuels at the Danforth Center and researchers at the U.S. Department of Energy Joint Genome Institute (DOE JGI), a DOE Office of Science User Facility, conducted genetic screens to identify genes that may play a role in flower development on the panicle of green foxtail. Green foxtail is a wild relative of the common crop foxtail millet. These *Setaria* species are related to several candidate bioenergy grasses including switchgrass and *Miscanthus* and serve as [grass](#) model systems to study grasses that photosynthetically fix carbon from CO₂ through a water-conserving (C₄) pathway. The genomes of both green foxtail and [foxtail millet](#) have been sequenced and annotated through the DOE JGI's Community Science Program.

"We have identified four recessive mutants that lead to reduced and uneven flower clusters," said Pu Huang, Ph.D., the lead author of the paper. "By ultimately identifying the gene in green foxtail we identified a new determinant in the control of grain yield that could be crucial to improving [food crops](#) like maize."

The grass *Setaria* has been proposed as a model for food and bioenergy crops for its short stature and rapid life cycle, compared to most bioenergy grasses. After constructing a mutant population resource for the grass, the Brutnell lab screened 2,700 M2 families, deep sequenced a mutant pool to identify the causative mutation and confirmed a homologous gene in maize played a similar role.

"Identifying this new player in panicle architecture may enable the design of plants with either enhanced or reduced panicle structures," stated Brutnell. "For instance, maize breeding has selected for reduced male panicles, also known as tassels, to reduce shading in the field while still producing sufficient pollen. However, grain yields in sorghum are directly related to the architecture of the panicle. By showing that this gene influences panicle architecture in *Setaria* and maize, we have expanded the tool box for breeders."

At the Danforth Center, plants hold the key to discoveries and products that will enrich and restore both the environment and the lives of people around the globe. Brutnell's lab research includes the search for the next generation of biofuels: alternative sources of energy that are affordable, sustainable and ecologically sound. The research develops novel computational tools and model systems to identify [genes](#) that will improve yield in [crops](#) through enhanced photosynthesis.
