(Phys.org)—A team of researchers with the Institute for Integrative Nanosciences in Germany has tested the possibility of using sperm cells to deliver drugs to cancerous tumors in female patients. In their paper uploaded to the preprint server *arXiv*, the group describes how such a technique might work, their initial test results and what they learned from their experiments.

In recent years, medical researchers have been focusing on developing carrier systems for delivery of chemicals to targets inside the body to treat ailments such as cancer, but thus far, it has been slow going due to a variety of issues such as the body responding in unhelpful ways or targets such as tumors putting up a tough front. In this new effort, the researchers looked into the idea of using a natural carrier to deliver helpful drugs to specified targets—sperm cells delivering drugs guided to tumors and other problem sites in the [female reproductive tract](#).

While it is known that sperm cells will swim around in the vagina searching for an egg to fertilize, and in some cases, have been known to swim up and fertilize eggs still in the fallopian tube, the randomness of their behavior was deemed too untenable for drug delivery—the team wanted to be able to steer individual sperm cells. To accomplish that feat, they coaxed sperm cells to swim into a very tiny helmet coated with iron that would adhere to its head. The sperm could then be steered using an external magnet. The helmet was designed with a quick-release mechanism that allowed it to dislodge from the sperm when it ran head first into something, such as a tumor cell, allowing the sperm cell to penetrate the tumor cell the same way it would an egg, delivering the drug. The researchers also found that they could cause a sperm cell to

absorb a cancer drug simply by soaking it in a solution containing the drug.

The researchers tested their idea using bull sperm on a tiny track in their lab. They report that they were able to successfully move the sperm cell to a desired location, HeLa cells and HeLa spheroids—stand-ins for [tumor cells](#). They report also that the helmet caused the sperm to swim 43 percent more slowly than normal. Though the [test results](#) proved impressive, there are many hurdles to overcome before such a technique could actually be used in humans—first and foremost, preventing accidental pregnancies. There is also the issue of what happens to the abandoned helmets (thousands would be left behind) and whether a [sperm cell](#) could be steered around inside the human body. And then there is the problem of obtaining the [sperm](#).

Abstract

A sperm-driven micromotor is presented as cargo-delivery system for the treatment of gynecological cancers. This particular hybrid micromotor is appealing to treat diseases in the female reproductive tract, the physiological environment that sperm cells are naturally adapted to swim in. Here, the single sperm cell serves as an active drug carrier and as driving force, taking advantage of its swimming capability, while a laser-printed microstructure coated with a nanometric layer of iron is used to guide and release the sperm in the desired area by an external magnet and structurally imposed mechanical actuation, respectively. The printed tubular microstructure features four arms which release the drug-loaded sperm cell in situ when they bend upon pushing against a tumor spheroid, resulting in the drug delivery, which occurs when the sperm squeezes through the cancer cells and fuses with cell membrane. Sperms also offer higher drug encapsulation capability and carrying stability compared to other nano and microcarriers, minimizing toxic effects and unwanted drug accumulation. Moreover, sperms neither express pathogenic proteins nor proliferate to form undesirable colonies, unlike other cells or microorganisms do, making this bio-hybrid system a unique and biocompatible cargo delivery platform for various biomedical applications, especially in gynecological healthcare.
