

New genetic technique could help identify potential drug targets for malaria

June 15 2017

Mosquito stage parasites generated by a genetic cross of parasites expressing either red or green fluorescence from the same location in the genome. Green and red parasites are the product of self-fertilization, so express only one fluorescent proteins. Orange parasites represent a cross of two parasites and express both fluorophores during development in the mosquito. Credit:

Scientists have developed a new technique for investigating the effects of gene deletion at later stages in the life cycle of a parasite that causes malaria in rodents, according to a new study in *PLOS Pathogens*. The novel approach, developed by Upeksha Rathnapala and colleagues at the University of Melbourne, Australia, could enhance research into potential drug targets for malaria treatment.

New treatments are needed for malaria because of increasing drug resistance in the single-celled *Plasmodium* [parasites](#) that cause it. Metabolic processes in *Plasmodium* that are essential for its development could serve as potential new [drug targets](#). However, the *Plasmodium* [life cycle](#), which occurs in both mosquitos and host animals, makes it difficult to identify and study such processes.

In the new study, the researchers demonstrate their novel technique by focusing on an important [metabolic process](#) in *Plasmodium berghei*, which causes malaria in rodents and is commonly used in mouse studies of malaria. This metabolic process requires a gene known as the ferrochelatase (FC) gene, and it allows *P. berghei* to produce a chemical compound known as heme.

Heme synthesis is known to be essential for *P. berghei* development in mosquitos that transmit the parasite between rodent hosts, but it is not essential during a later stage in the host bloodstream. However, between these two stages, *P. berghei* undergoes a developmental phase in the host [liver](#), and it has been unclear whether heme synthesis is essential at this stage.

Rathnapala and colleagues produced *P. berghei* parasites that are capable

of expressing the FC gene and developing properly in mosquitos, but produce a mix of FC-expressing and FC-deficient parasites once they infect mouse liver cells. The scientists genetically engineered the parasites so that FC-deficient individuals would express fluorescent markers, allowing for easy identification.

The researchers found that FC-deficient parasites were unable to complete their liver development phase. This suggests that disrupting the heme synthesis pathway could be an effective way to target *Plasmodium* parasites in the liver. Such an approach would be prophylactic, since symptoms aren't apparent until the parasite leaves the liver and begins its bloodstream phase.

This same novel approach involving fluorescent markers could be adapted for other genes, allowing scientists to identify additional metabolic processes that are essential for *Plasmodium* development in host animals.

"The idea of tagging mutant genes with fluorescent proteins is a simple one but it allowed us to follow mutant parasites throughout the malaria life cycle and dissect their phenotypes in the liver stage, something that hasn't been easy to do for mutations that block mosquito development," the author explain. "Our analysis of heme biosynthesis shows the power of this simple method but It's a technique that can be easily applied to other [genes](#) and other malaria parasite species, greatly expanding the scope for investigating this immunologically important stage in the [malaria](#) parasite's life cycle."
