

Adding organic matter to soil has a limited effect on water holding capacity

Sequestering carbon in the soil via the addition of organic matter has

been widely promoted for the mitigation of climate change. Enhancing soil organic matter can improve soil quality, i.e., increasing nutrient retention, improving soil structure, enhancing soil biotic activity and improving soil moisture and temperature regimes. Adding organic matter has also been widely promoted for increasing soil's water holding capacity. It was suggested as a means to buffer yields against future variable weather conditions.

While the positive [effect](#) of OM on soil water retention is much studied and widely promoted, there is still no clear consensus on its quantitative effect. The increase in the amount of water that is available to plants with an increase in [organic matter](#) is still uncertain and maybe overestimated. To clarify this issue, researchers from the Sydney Institute of Agriculture at the University of Sydney conducted a critical review now published in the *European Journal of Soil Science*. They evaluated data from 60 published studies and analysed large databases of soil water (more than 50,000 measurements globally) seeking relations between [organic carbon](#) (OC) and [water content](#) at saturation, field capacity, wilting point and available water capacity.

From this first comprehensive review, the authors found that the effect of adding OM to soil enhanced available water capacity only modestly, with an average value of between 1.5 to 2.0 mm per m with 1 percent mass increase in organic carbon. Sandy soil was more responsive to the increase in OM, whereas the effect on clayey soil was almost negligible. The largest effect of OC was in large pores, possibly from the formation of large aggregates, and its effect decreases with a decrease in the size of the pores.

An average 1 percent mass increase in soil organic carbon (or 10 g C per kg soil mineral) increases water content at saturation, field capacity, wilting point and available water capacity by three, 1.6, 0.2 and 1.2 mm water per m of soil. Compared with reported annual rates of carbon

sequestration after the adoption of conservation agricultural systems, the effect on soil available water is negligible. Thus, arguments for sequestering carbon to increase water storage are questionable.

The results also suggest that the gradual loss of organic matter from soil would have a minimal effect on the hydrological cycle. Global warming might cause a loss in soil carbon, but the effects on [soil water](#) availability to plants and its consequent effect on the hydrological cycle might be less than previously thought.

However, the authors note that this study does not suggest that farms should not increase soil's organic matter. When the soil organic carbon content falls below 1 percent, the soil is endangered, as the soil aggregates become destabilized and soil nutrient cycling is compromised. Increasing [carbon](#) in the soil should still be pursued for improving soil structure, atmospheric CO₂ attenuation and nutrient cycling. Macropores created by organic matter can still have important effects in increasing water infiltration and gas transport. In addition, adding OM can create a mulching effect that reduces soil evaporation, and thus increases [soil water](#) content.
