The molten surface of a sodium-based material could assist the direct

conversion of methane to useful building blocks.

For [natural gas](#) to be efficiently converted into useful industrial products requires the right catalytic process. Researchers from KAUST and the US combine state-of-the-art techniques for material characterization to demonstrate a unique [reaction](#) pathway that shows that molten catalysts based on sodium can provide all the chemical species required to optimize the process.

Free radicals, molecules with an unpaired valence electron, such as the hydroxyl radical, play a crucial role in the industrially important conversion of natural gas, primarily methane, to ethylene: a vital organic compound that forms the [building blocks](#) of many commodities and polymers. To enhance this process, known as oxidative coupling, it is vital to develop selective catalysts.

The KAUST team—led by Kazuhiro Takanabe and his student Abdulaziz Khan—used in situ tools to measure the state of a [catalyst](#) under reaction conditions. They discovered that the active species in the catalytic reaction that exists on the molten surface of the sodium tungstate, a chemical necessary for the reaction, is sodium peroxide. This catalyst is unique in that instead of activating methane directly, it firsts activates water and then generates gaseous hydroxyl radicals.

Oxidative coupling of methane converts methane and oxygen to ethylene in a single reactor. Previous research in Takanabe's lab had indicated that by using sodium tungstate at temperatures above 700 °C, the presence of water can both increase the rate of [methane](#) conversion and enhance product selectivity. This could potentially occur via the formation of hydroxyl radicals and sodium peroxide, but there was no direct evidence for the presence of these species.

Now, Takanabe and his co-authors provide direct evidence for the

formation of these [free radicals](#) on the molten surface of sodium tungstate. They combine a wide range of experimental techniques, including X-ray diffraction, scanning transmission electron microscopy, laser-induced fluorescence spectrometry and X-ray photoelectron spectroscopy, to observe an outer layer of molten sodium tungstate that is rich in sodium hydroxide. "We exclusively identified the catalyst's active phase in a unique state under reaction conditions," explains Takanabe.

This in turn confirms that a [sodium](#)-based catalyst can form [hydroxyl radicals](#) from a mixture of oxygen and water, a reaction that has never been seen. "This catalyst and the unique reaction pathway have great potential for use in various catalytic reactions for natural gas conversion, petroleum refinery and combustion reactions," says Takanabe.

More broadly, this success also demonstrates the importance of combining in situ spectroscopic and microscopic techniques to better understand high-temperature gas-phase chemistry.
