An international team of researchers has found that new particle formation (NPF) can occur in the atmosphere even in heavily polluted air. In their paper published in the journal *Science*, the group describes

air quality testing they did in China over a period of years and what they found.

NPF occurs in the atmosphere when certain ingredients clump together spontaneously, causing the formation of new [particles](#). Prior research has suggested that NPF only occurs in relatively pristine air, because particles in polluted air tend to scavenge precursors. In this new effort, the research team has found evidence indicating such conclusions are wrong—they have found evidence of NPF occurring in a heavily populated and polluted part of China.

The researchers explain that understanding NPF is important because of the impact it has on global warming. They note that NPFs can lead to cloud formation of a type that traps heat. To learn more about them and air pollution in China in general, they set up air quality monitoring stations in Shanghai and studied data from them covering the years 2014 to 2017.

In analyzing the chemistry of particles captured by the monitoring stations, the researchers found evidence of NPF precursor vapors and also large amounts of actual NPF clusters—this, despite the presence of large amounts of other particulates in the air. They suggest the NPF events came about due to sulfuric acid-dimethylamine-water nucleation which included sulfuric acid dimers.

To better understand how such clusters might form, the researchers entered their real-world data into a model and ran simulations to mimic conditions in the air over Shanghai and other large cities in China. They found that concentrations of sulfuric acid were sufficient to explain particle formation and growth during times of high condensation. They also found evidence that suggested larger cluster growth was likely due to the presence of other condensing organic species.

The researchers claim their study not only shows that NPF can occur in heavily polluted air, but that it is likely having a bigger impact on [global warming](#) than has been thought. They suggest climate change models will need to be changed to reflect what they have found.

Abstract

Atmospheric new particle formation (NPF) is an important global phenomenon that is nevertheless sensitive to ambient conditions. According to both observation and theoretical arguments, NPF usually requires a relatively high sulfuric acid (H_2SO_4) concentration to promote the formation of new particles and a low preexisting aerosol loading to minimize the sink of new particles. We investigated NPF in Shanghai and were able to observe both precursor vapors (H_2SO_4) and initial clusters at a molecular level in a megacity. High NPF rates were observed to coincide with several familiar markers suggestive of H_2SO_4 –dimethylamine (DMA)–water (H_2O) nucleation, including sulfuric acid dimers and H_2SO_4 -DMA clusters. In a cluster kinetics simulation, the observed concentration of sulfuric acid was high enough to explain the particle growth to ~3 nanometers under the very high condensation sink, whereas the subsequent higher growth rate beyond this size is believed to result from the added contribution of condensing organic species. These findings will help in understanding urban NPF and its air quality and climate effects, as well as in formulating policies to mitigate secondary particle formation in China.
