NUS scientists have developed multibit optoelectronic memory using a heterostructure made of two-dimensional (2-D) materials for next generation devices.

Optoelectronic memories are devices which can store photon-generated charge carriers when exposed to light. The stored charges can be accessed later for information retrieval. These devices can be used in image capture and spectrum analysis systems. 2-D atomically layered materials are promising candidates for the development of next generation [optoelectronic](#) memories to meet emerging requirements for device miniaturisation and structural flexibility. However, optoelectronic memories fabricated using 2-D materials have been reported to suffer from poor data storage capability with the highest reported figure at about eight distinct storage states.

A team lead by Prof Chen Wei from both the Department of Chemistry and the Department of Physics, NUS has developed a multibit, non-volatile optoelectronic memory device that is able to store up to 130 distinct states by using a tungsten diselenide/boron nitride ( $\text{WSe}_2/\text{BN}$ ) heterostructure. The heterostructure, made of 2-D [materials](#), comprises a monolayer of  $\text{WSe}_2$  on a 20-layer BN. The programming (store data) and erasing (delete data) functions are controlled by adjusting the applied polarity to the device. A negative polarity is applied during the programming function and it causes the photon-generated electrons from the midgap donor-like states of the BN material to transfer into the  $\text{WSe}_2$  material. This leaves behind localised (non-mobile) positive charges in the BN material. For the erasing function, a positive polarity is applied. This causes the photon-generated electrons from the valence band in the BN material to recombine with the localised positive charges, returning it to a neutral state.

The amount of electrons transferred into the  $\text{WSe}_2$  material is dependent on the duration of light exposure time for the device. A longer exposure time would mean that more electrons are transferred. The researchers found that the continual accumulation of electrons in the  $\text{WSe}_2$  material corresponding up to 130 light pulses can be detected before saturation conditions set in. Each of these pulses can be treated as a distinct storage

state. During performance testing, they found that the device exhibits a data retention of over  $4.5 \times 10^4$  seconds and a cyclic programme/ erase endurance exceeding 200 cycles.

Explaining the significance of the findings, Prof Chen said, "Although there is still a performance gap when compared to commercial silicon-based memory, these devices are advantageous in electronic applications which require structural flexibility. The use of this  $\text{WSe}_2/\text{BN}$  2-D layered heterostructure provides a method to achieve multibit [memory](#) device and may pave the way for the development of next generation optoelectronic memories."
