

Researchers find precipitation thresholds regulate carbon exchange

September 26 2018

Sensitivity of ecosystem production and respiration to precipitation showed a threshold behavior over the contiguous United States. Credit: Courtesy of Zhihua Liu

One of the major sources of uncertainty about the future climate is whether ecosystems will continue to take up carbon dioxide or release it

to the atmosphere. University of Montana researchers and co-authors confronted this problem using atmospheric measurements and satellite observations to test model simulations in a recent study published on Sept. 5 in *Nature Communications*.

W.A. Franke College of Forestry and Conservation Research Scientist Zhihua Liu and colleagues compared atmospheric measurements and [satellite observations](#) to climate change [model simulations](#) to help better predict terrestrial [carbon](#) dynamics across the contiguous United States.

Ecosystems either soak up carbon through photosynthesis—a negative feedback that could reduce future warming—or release it through respiration—a positive feedback that could enhance future warming. Understanding how climate change might impact ecosystem photosynthesis and respiration is critical for predicting future carbon dynamics.

Liu's team discovered that whether ecosystems across the U.S. uptake carbon or release it is dependent on water availability. The primary control switches from production to respiration at an annual precipitation threshold between 30 and 35 inches in the contiguous United States. The carbon balance of ecosystems in the dry West is very sensitive to photosynthesis. In contrast, the carbon balance of more mesic Eastern U.S. ecosystems is more sensitive to carbon lost through respiration.

However, climate models do not reflect this precipitation threshold. Liu and his co-authors determined that these models are far too sensitive to photosynthesis and not sensitive enough to respiration, suggesting the Earth's [ecosystems](#) may lose more carbon to the atmosphere in the future as surface temperatures continue to warm.

"In different regions, the interannual variation of net carbon uptake is primarily impacted by different processes—respiration or

photosynthesis," Liu said. "To me, the most important part of this study is that the models need improvement on [respiration](#)."

Co-author and UM bioclimatology Associate Professor Ashely Ballantyne adds, "This study suggests we know more about the negative feedback loop and less about the positive one."
