

## The orderly chaos of black holes

January 14 2019

The dedicated Gamma-ray Burst Polarimetry experiment POLAR on top of China's TiangGong-2 spacelab launched on Sept. 15, 2016. The glowing green light mimics the scintillating light when a gamma-ray photon hits one of the 1,600 specially made scintillation bars. The artwork is based on a picture taken by a camera located several meters behind POLAR. Credit: Institute of High Energy Physics

During the formation of a black hole, a bright burst of very energetic light in the form of gamma rays is produced, these events are called gamma ray bursts. The physics behind this phenomenon includes many of the least understood fields within physics today: general gravity, extreme temperatures and acceleration of particles far beyond the energy of the most powerful particle accelerators on Earth.

In order to analyse these gamma ray bursts, researchers from the University of Geneva (UNIGE), in collaboration with the Paul Scherrer Institute (PSI) of Villigen, Switzerland, the Institute of High Energy Physics in Beijing and the National Center for Nuclear Research of Swierk in Poland, built the POLAR instrument to analyze gamma ray bursts, which was sent in 2016 to the Chinese Tiangong-2 space laboratory. Contrary to prevailing theories, the first results of POLAR reveal that the high energy photons coming from gamma ray bursts are neither completely chaotic, nor completely organized, but a mixture of the two: Within short time intervals, the photons are found to oscillate in the same direction, but the oscillation direction changes with time. These unexpected results are reported in a recent issue of the journal *Nature Astronomy*.

When two <u>neutron stars</u> collide or a super-massive star collapses into

itself, a black hole is created. This birth is accompanied by a gamma ray burst (GRB)—a very energetic light wavelength such as that emitted by radioactive sources.

## Is the black hole birth environment organized or chaotic?

How and where the gamma rays are produced is still a mystery, and there are two schools of thought on their origin. The first predicts that photons from GRBs are polarized, meaning the majority of them oscillate in the same direction. If this were the case, the source of the photons would likely be a strong and well-organized magnetic field formed during the violent aftermath of the black hole production. A second theory suggests that the photons are not polarized, implying a more chaotic emission environment. But how to check this?

"Our international teams have built the first powerful and dedicated detector, called POLAR, capable of measuring the polarization of gamma rays from GRBs. This instrument allows us to learn more about their source," said Xin Wu, professor in the Department of Nuclear and Particle Physics of the Faculty of Sciences of UNIGE. Its operation is simple. It is a square of  $50 \times 50 \text{ cm}^2$  consisting of 1600 scintillator bars in which the gamma rays collide with the atoms that make up these bars. When a photon collides in a bar, we can measure it. Afterwards, it can produce a second photon which can cause a second visible collision. "If the photons are polarized, we observe a directional dependency between the impact positions of the photons, continues Nicolas Produit, researcher at the Department of Astronomy of the Faculty of Sciences of UNIGE. On the contrary, if there is no polarization, the second photon "esulting from the first collision will leave in a fully random direction."

## Order within chaos

In six months, POLAR has detected 55 gamma ray bursts, and scientist analyzed the polarization of gamma rays from the five brightest ones. The results are surprising, to say the least. "When we analyse the polarization of a gamma ray burst as a whole, we see at most a very weak polarization, which seems to clearly favour several theories," says Merlin Kole, a researcher at the Department of Nuclear and Particle Physics of the Faculty of Sciences of UNIGE and one of the main authors of the paper.

Faced with this first result, the scientists looked in more detail at a very powerful nine-second long gamma ray burst and cut it into time intervals of two seconds. "There, we discovered with surprise that, on the contrary, the photons are polarized in each slice, but the oscillation direction is different in each slice," Xin Wu says. It is this changing direction that makes the full GRB appear as very chaotic and unpolarized. "The results show that as the explosion takes place, something happens that causes the photons to be emitted with a different polarization direction. What this could be, we really don't know," says Kole.

These first results confront the theorists with new information, requiring them to produce more detailed predictions. "We now want to build POLAR-2, which will be bigger and more precise. With that, we can dig deeper into these chaotic processes to discover the source of the gamma rays and unravel the mysteries of these highly energetic physical processes," explains Nicolas Produit.
