

Origin of the saffron crocus traced back to Greece

April 3 2019

The origin of *C. sativus* has long been the subject of speculation and research, as this knowledge would enable breeders to introduce genetic diversity into the otherwise genetically uniform plant species. Two new studies have now shown that the saffron crocus originated from a Greek ancestor.

Since ancient times, saffron has given dishes a golden-yellow hue and an aromatic flavour. The use of the stigmas of the saffron crocus (*Crocus sativus*) is depicted in frescos from Crete and Santorini, which are as old as 3600 years. Nowadays, the valuable plant is mainly cultivated in Iran accounting for more than 90 percent of the saffron production. Due to its hardiness, small batches of the saffron crocus are even grown and harvested in more unlikely countries such as Switzerland and Germany. Possibly partially due to its widespread agricultural adoption, the origin of saffron has until recently been a subject of speculation. Now, two independent studies have been able to trace the roots of *C. sativus* back to Greece.

The saffron crocus is a triploid and male-sterile plant. This means that the plant can only be propagated vegetatively. In this case, parts of the corms (bulb-like structures of the stem) of the saffron plants are broken off and then these daughter-corms are used to grow new adult plants. A consequence of this form of reproduction is that there is no room for improving saffron quality by crossing different cultivars. Thus, all modern saffron plants are genetically nearly identical. Knowing the origin, in particular the originating plant species, would enable saffron breeders to use new genotypes to broaden the diversity of the saffron crocus.

Researchers of the Leibniz Institute of Plant Genetics and Crop Plant Research (IPK Gatersleben) decided to tackle the mystery of saffron's origin by comparing molecular markers of wild crocus species with those of cultivated saffron crocus. In the research group of Frank Blattner, plant material was obtained through sample-collecting excursions from native stands of all relevant species. Through the analyses of genome-wide single-nucleotide polymorphisms (SNPs) and the investigation of the chloroplast genomes of the different crocus

species, the researchers were able to pinpoint the species with the highest genetic similarity to *C. sativus*. As such, the wild crocus species *C. cartwrightianus* from Greece was identified as the sole progenitor of the modern saffron plant, and the area in the vicinity of the Greek capital Athens as the region where it evolved.

C. cartwrightianus had already been postulated as a possible progenitor of *C. sativus*, however the high intra-specific [genetic diversity](#) present in *C. cartwrightianus* had led to unclear results during previous investigations. Now, in the IPK-study, an unambiguous total of 99.3 percent of the alleles of *C. sativus* could be recovered in *C. cartwrightianus*.

These results were confirmed by an independent complementary study performed by researchers at TU Dresden. The Dresden scientists in Thomas Schmidt's group performed comparative chromosome analysis with fluorescence in situ hybridization (FISH) of different crocus [species](#), and could also demonstrate that *C. sativus* resulted from the fusion of the genomes of two *C. cartwrightianus* [plants](#), an event called "autopolyploidisation."

A slight surprise for all of the involved researchers was that the main growing regions for saffron are clearly located outside the distribution area of its progenitor *C. cartwrightianus*, with *C. sativus* prospering in drier regions and at higher elevations. They suspect that the explanation to this also lies within the origin story of saffron—it was probably the genome-fusing autopolyploidisation event that led to ecological shift of [saffron](#), away from the habitats in the Mediterranean vegetation zone of Greece.
