Incorporating cover crops with tillage reportedly results in increased cover crop decomposition rates and increased mineralization of nutrients from cover crop biomass. Multiple studies have reported mixed results for corn-soybean grain yields when planted after cover crops.

In an [article](#) recently published in *Agronomy Journal*, researchers reported results of a four-year study on corn-soybean rotation. Treatments were completed under either conventional tillage or no-tillage, and with and without cover crop. Researchers included three rotations: cereal rye-soybean-hairy vetch-corn, cereal rye-soybean-oat+radish-corn, and no cover crop-soybean-no cover crop-corn.

The team found that rotation with hairy vetch as a preceding cover crop increased corn grain yield by 14.09 and 12.35% compared to rotations having no cover crop and oat+radish as preceding cover crops, respectively. Cereal rye cover crop biomass had 16-20 kg ha⁻¹ greater N uptake compared to winter annual weeds in rotation without cover crops. Researchers reported that cereal rye preceding soybean reduced soybean yield by 0.3 to 0.6 Mg ha⁻¹ compared to soybean following no cover crop.

Cover crops are touted for their soil and [water quality](#) related benefits. However, their adoption and success will depend on the selection of [cover crop](#) species available that do not reduce grain yields in following crops.
