The roar of a lion is one of the most thrilling and captivating sounds of the wild. This characteristic call is typically delivered in a bout consisting of one or two soft moans followed by several loud, full-throated roars and a terminating sequence of grunts.

A team of scientists based in WildCRU at the University of Oxford, well-known for their research involving Cecil the Lion, has teamed up with colleagues in the Department of Computer Science to discover the precise ways in which each [lion](#)'s roar is distinct, identifiable and trackable.

Harnessing new machine learning techniques, the group designed a device, known as a bilogger, which can be attached to an existing lion GPS collar to record audio and movement data. The loggers allow the scientists to confidently associate each roar with the correct lion by cross-referencing movement and [audio data](#) through the large datasets of roar recordings collected.

With the data collected by the loggers, the scientists trained a pattern recognition algorithm to "learn" each individual's roars and then tested the algorithm on sequences that it had not seen before to determine whether the shape of the contour as a whole is an important distinguishing feature.

Results, published in *Bioacoustics*, reveal that it is possible to classify roars according to individual [identity](#) with 91.5% accuracy. These findings suggest that the overall shape of the fundamental frequency (f_0) of the full-throated roar contour is consistent within each individual's roars and sufficiently different from other individuals to allow for accurate classification of individual identity.

Previous research has shown that lions can recognize the calls of other individuals, allowing them to locate distant companions and also to avoid

potentially hostile neighbors. But little has been understood about how individuals convey identity information in the structure of their calls.

These new findings reveal a possible mechanism for individual vocal recognition amongst African lions. They indicate that individual lions may be able to learn the subtle variations in the fundamental frequency of other lions' roars and thereby associate particular variations with particular identities.

Andrew J. Loveridge, from WildCRU at the Department of Zoology, said: "African lion numbers are declining and developing cost effective tools for monitoring, and ultimately better protecting, populations is a conservation priority. The ability to remotely evaluate the number of individual lions in a population from their roars could revolutionize the way in which lion populations are assessed."

Andrew Markham, from the Department of Computer Science at Oxford, said: "Being able to accurately distinguish between individual roars using machine learning algorithms could facilitate the development of alternative techniques for assessing [population](#) density and tracking individual movements across the landscape."

The scientists plan to develop their work by carrying out play-back experiments using modified calls. They hope that they will be able to determine whether the fundamental frequency alone conveys sufficient information on [individual identity](#) to enable vocal recognition. With rapid technological advances, automated acoustic monitoring of lion populations may not be far off.
