

## Carbon dioxide feeds plants, but are Earth's plants getting full?

December 11 2020, by Amanda Cavanagh and Caitlin Moore

Plants do a lot of work for us, producing the air we breathe, the food we

eat, and even some of our medicine. But when it comes to removing carbon dioxide in the atmosphere, we may have been overestimating their ability.

Photosynthesis acts as the lungs of our planet—plants use light and <u>carbon dioxide</u> (CO<sub>2</sub>) to make the sugars they need to grow, releasing oxygen in the process. When atmospheric CO<sub>2</sub> concentrations increase, as they have been thanks to humans burning fossil fuels, one might think that plants are enjoying a smorgasbord of food for unlimited growth. But a new study published in <u>Science</u> shows this excess of riches is not as effective as previously thought.

Since  $CO_2$  is the main source of food for plants, increasing levels of it directly stimulate the photosynthetic rate of most plants. This <u>boost in</u> <u>photosynthesis</u>, known as the "CO<sub>2</sub> fertilization effect," enhances growth in many of earth's plant species, with the effects seen most clearly in <u>crops</u> and young trees, and less so in <u>mature forests</u>.

The amount of  $CO_2$  used by photosynthesis and stored in vegetation and soils has grown over the past 50 years, and now absorbs at least a quarter of human emissions in an average year. We've been assuming that this benefit will continue to increase as  $CO_2$  concentrations rise, but data collected over a 33-year period show us that might not be true.

## Fertilization is in decline

Estimating the size of the global  $CO_2$ -fertilization effect accurately is no easy task. We have to understand what limits photosynthesis from one region to another, and at every scale from molecules within a leaf through to whole ecosystems.

The big research team behind the new *Science* study used a combination of data from satellites and on-the-ground observations and models of the

carbon cycle. Using this powerful toolkit, they found that the fertilization effect declined across much of the globe from 1982 to 2015—a trend that correlates well with observed changes in <u>nutrient</u> <u>concentrations</u> and available <u>soil water</u>.

FLUXNET towers around the world measure the exchanges of carbon dioxide, water vapor, and energy between the biosphere and atmosphere. Credit: Caitlin Moore, Author provided

In many ways, the combination of these different tools helps to paint a more complete picture of how the world's ecosystems are

photosynthesising. The researchers <u>used</u> a collection of long-term measurements from <u>flux towers</u> like the one pictured below which continuously monitor the  $CO_2$  and water used by plants and are dotted across earth's biomes and provide the best means of measuring photosynthesis at the ecosystem scale.

Flux towers are limited in their measurement range (1 km or so) – but the data these towers collect helps verify the satellite estimates of how much photosynthesis is going on. With satellites and flux towers now providing records since the 1990s (and earlier in some cases), scientists are able to assess long-term trends in global photosynthesis. These can then be compared to "models"—the computer-based simulations predicting plant–environment interactions—as the researchers did in this recent study.

## What might the models be missing?

Researchers in the latest study found that the decrease in  $CO_2$ fertilization was related to the availability of nutrients and water, which the computer simulations might not be accounting for properly. We know that nutrients such as nitrogen and phosphorus are <u>declining</u>) in some areas—which may be unaccounted for. Plants can also acclimate, or change how they grow, when the environment changes.

Just like we can spend less on groceries when food is plentiful, plants invest less nitrogen in photosynthesis when they are grown at high  $CO_2$ . When this happens,  $CO_2$  fertilization is less effective than before. Because some plants have a stronger response than others, the response can be difficult to account for in computer simulations.

For many years, some people have assumed that carbon fertilization will mitigate climate change by slowing the rate at which  $CO_2$  is increasing in the atmosphere. Although the effect is built into the models used to

predict future climates, the argument has <u>become widely misinterpreted</u> by those who believe the world is overreacting to <u>climate change</u>.

But if the new study is right, and we have indeed been overestimating the amount of carbon that <u>plants</u> will pull from the atmosphere in the future, even our most cautious climate projections have likely been optimistic.
