

Start small to answer the big questions about photosynthesis

March 11 2021

Light is absorbed by light-harvesting proteins in the plant membrane. The energy excites the proteins and the way they arrange themselves determines the way energy is transferred through the plant. Credit: Sophie Meredith, University of Leeds

New scientific techniques are revealing the intricate role that proteins play in photosynthesis.

Despite being discovered almost 300 years ago, [photosynthesis](#) still holds

many unanswered questions for science, particularly the way that proteins organize themselves to convert sunlight into [chemical energy](#) and at the same time, protect plants from too much sunlight.

Now a collaboration between researchers at the University of Leeds and Kobe University in Japan is developing a novel approach to the investigation of photosynthesis.

Using hybrid membranes that mimic natural plant membranes and advanced microscopes, they are subjecting photosynthesis to nanoscale investigation—the study of life at less than one billionth of a meter—to reveal the behavior of individual [protein](#) molecules.

Dr. Peter Adams, Associate Professor in the School of Physics and Astronomy at the University of Leeds, who supervised the research, said: "For many decades scientists have been developing an understanding of photosynthesis in terms of the biology of whole [plants](#). This research is tackling it at the [molecular level](#) and the way proteins interact.

"A greater understanding of photosynthesis will benefit humankind. It will help scientists identify new ways to protect and boost crop yields, as well as inspire technologists to develop new solar-powered materials and components."

The findings are published in the academic journal *Small*.

Photosynthesis happens when photons or packets of light energy cause pigments inside light-harvesting proteins to become excited. The way that these proteins arrange themselves determines how the energy is transferred to other molecules.

It is a complex system that plays out across many different pigments, proteins, and layers of light-harvesting membranes within the plant.

Together, it regulates energy absorption, transfer, and the conversion of this energy into other useful forms.

To understand this intricate process, scientists have been using a technique called atomic force microscopy, which is capable of revealing components of a [membrane](#) that are a few nanometres in size.

The difficulty is that natural plant membranes are very fragile and can be damaged by atomic force microscopy.

But last year, the researchers at Kobe University announced that they had developed a hybrid membrane made up of natural plant material and synthetic lipids that would act as a substitute for a natural plant membrane—and crucially, is more stable when placed in an atomic force microscope.

The team at the University of Leeds used the hybrid membrane and subjected it to atomic force microscopy and another advanced visualization technique called fluorescence lifetime imaging microscopy, or FLIM.

Ph.D. researcher Sophie Meredith, also from the School of Physics at the University of Leeds, is the lead author in the paper. She said: "The combination of FLIM and [atomic force microscopy](#) allowed us to observe the elements of photosynthesis. It gave us an insight into the dynamic behaviors and interactions that take place.

"What is important is that we can control some of the parameters in the hybrid membrane, so we can isolate and control factors, and that helps with experimental investigation.

"In essence, we now have a 'testbed' and a suite of advanced imaging tools that will reveal the sub-molecular working of photosynthesis."
