

# NASA's mineral dust detector starts gathering data

July 30 2022, by Jane J. Lee, Andrew Wang

This image shows the first measurements taken by EMIT on July 27, 2022, as it passed over Western Australia. The image at the front of the cube shows a mix of materials in Western Australia, including exposed soil (brown), vegetation (dark green), agricultural fields (light green), a small river, and clouds. The

rainbow colors extending through the main part of the cube are the spectral fingerprints from corresponding spots in the front image. The graph on the right shows spectral fingerprints for a sample of soil, vegetation, and a river from the image cube. Credit: NASA/JPL-Caltech

After being installed on the exterior of the International Space Station, NASA's Earth Surface Mineral Dust Source Investigation (EMIT) mission has provided its first view of Earth. The milestone, called "first light," took place at 7:51 p.m. PDT (10:51 p.m. EDT) on July 27 as the space station passed over Western Australia.

Developed by NASA's Jet Propulsion Laboratory in Southern California, EMIT is focused on mapping the mineral dust composition of Earth's [arid regions](#) to better understand how dust affects climate heating and cooling. The instrument works by measuring the hundreds of wavelengths of light reflected from materials on Earth. Different substances reflect different [wavelengths of light](#), producing a kind of spectral fingerprint that, when collected by an imaging spectrometer and analyzed by researchers, reveal what they are made of.

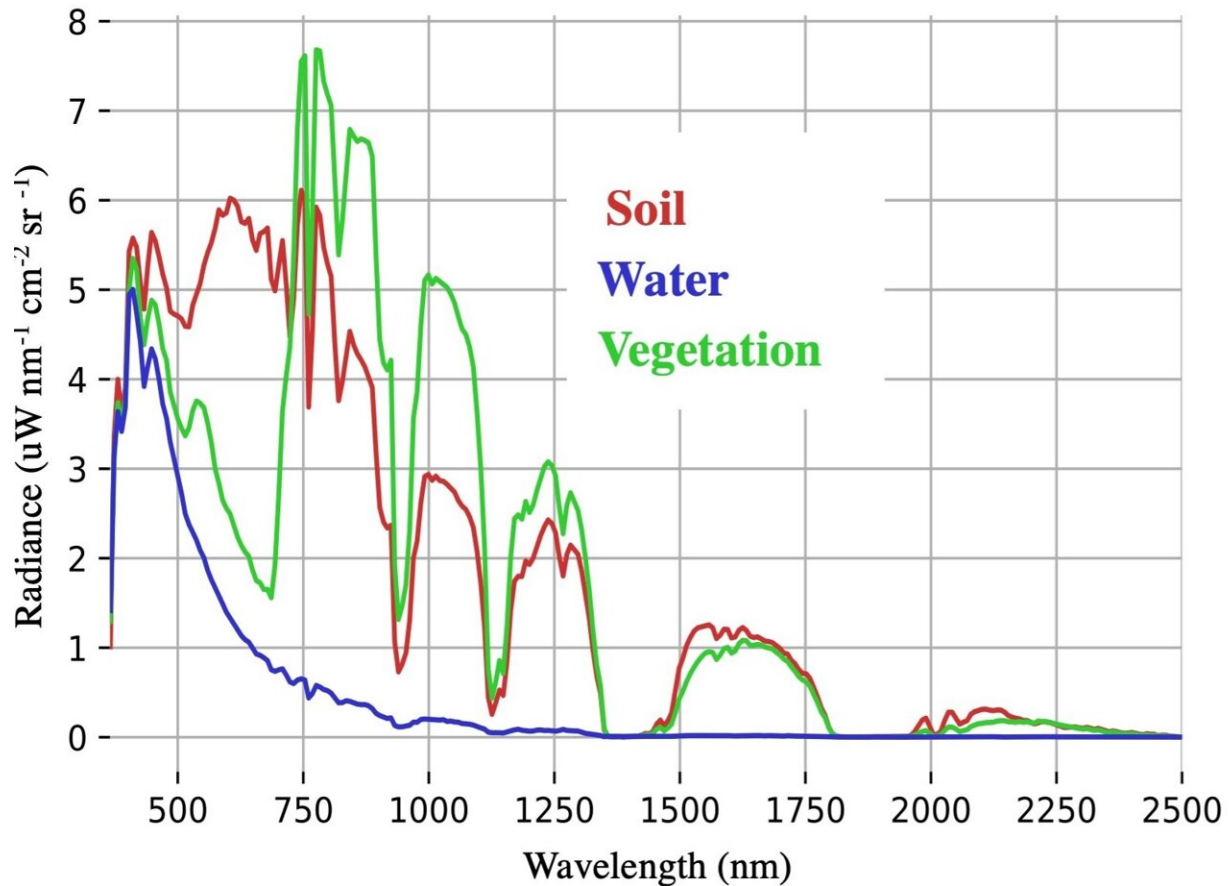

Ground controllers used the Canadarm2 robotic arm of the [space station](#) to remove EMIT from a Dragon spacecraft and install it on the outside of the station, a process that began on July 22 and took more than 40 hours. Engineers powered on the instrument on July 24 and cooled it to its operating temperature over the next 72 hours.

The EMIT team then collected the instrument's first measurements, creating something called an image cube. The image at the front of the cube shows a mix of materials in Western Australia, including exposed soil (brown), vegetation (dark green), [agricultural fields](#) (light green), a small river, and clouds. The rainbow colors extending through the main

part of the cube are the spectral fingerprints from corresponding spots in the front image.

While the EMIT instrument can measure the spectral signature of light from such materials as vegetation, rocks, snow and ice, and human-made surfaces, its primary mission, beginning in August, will be to collect measurements of 10 important surface minerals (hematite, calcite, dolomite, and gypsum, for example) in arid, dust-producing regions of Africa, Asia, North and South America, and Australia.

The spectral fingerprints of dust minerals allow scientists to determine its composition. While dark, iron-rich particles strongly absorb the Sun's energy, light-colored clays reflect it. Right now, scientists don't know whether mineral dust has a cumulative heating or cooling effect on the planet. The full spectral fingerprints that EMIT collects will help answer that question.

The line graph shows spectral fingerprints for soil, vegetation, and a river. Radiance indicates the amount of each wavelength of light (in nanometers) reflected from a substance. Credit: NASA/JPL-Caltech

EMIT was developed at NASA's Jet Propulsion Laboratory, which is managed for the agency by Caltech in Pasadena, California. It launched aboard a SpaceX Dragon resupply spacecraft carrying more than 5,800 pounds of science experiments, crew supplies, and other cargo from NASA's Kennedy Space Center in Florida on July 14. The instrument's data will be delivered to the NASA Land Processes Distributed Active Archive Center (DAAC) for use by other researchers and the public.
