TOMOGRAPHY IN FLOW CYTOMETRY

ILLUMINATION SCANNING-BASED TOMOGRAPHY

Optical configurations used for tomographic imaging of cells. Sketches of optical system configurations used for recording tomographic data (A) in flow cytometry condition, referring to setups A and B, and (B) by illumination scanning-based arrangement used in setup C. HWP, half-wave plate; PBS, polarized beam splitter; MO, microscope objective; L, regular lens; M, mirror; SLM, spatial light modulator; BS, beam splitter; OBJ, objective lens. In (B), the SLM is used to change the illumination angle of the incident beam by modulating the phase of the incident beam. The SLM is conjugated to the imaging plane where the sample is located (the red blob between OBJ1 and OBJ2) and conjugated to the camera's detection plane. Reference arm is added to interfere with the sample beam for off-axis holographic detection using a beam splitter. The corresponding processing pipelines for the tomographic reconstruction of data collected from (A) and (B) are reported in the bottom, respectively. Credit: *Intelligent Computing* (2023). Single-cell analysis is a powerful biomedical technique used in various fields of biology and medicine to identify rare cell populations, track cell development and differentiation, understand disease mechanisms and develop personalized therapies, but it generates large amounts of data that can be difficult to manage.

An international team of researchers led by Demetri Psaltis of the Swiss Federal Institute of Technology Lausanne and Pietro Ferraro of the Institute of Applied Sciences and Intelligent Systems has demonstrated an effective encoding strategy for single-cell tomograms that greatly streamlines the handling and storage of single-cell data while maintaining fidelity.

Their research was published Jan. 11 in *Intelligent Computing*.

The new method proposed by the authors can effectively manage and

process the vast datasets generated by tomographic phase microscopy, a popular technique for single-cell studies. This technique can rapidly produce 3D images of living [cells](#) and tissues without damaging the sample, making it a [valuable tool](#) for studying cellular dynamics such as division, migration and differentiation.

A major challenge currently faced in tomographic phase microscopy is effectively managing massive quantities of 3D data to achieve swift and accurate cellular diagnosis. The new method can achieve a data compression ratio of 22.9. This means that big-data single-cell tomograms can be compressed while saving over 95% of space, with less than 1% of information lost.

The strategy works well on various experimental data, including different types of cells with spherical and non-spherical shapes. In fact, it can efficiently process any volumetric images.

In the future, it will be possible to have a lab-on-a-chip tomographic imaging flow cytometry system—a system that employs lasers to measure various characteristics of individual cells as they move through a fluid-filled channel. To achieve this will require a microfluidic module capable of controlling the positions and rotation of the flowing cells using advanced cell manipulation solutions such as multicore fiber.

From the computational point of view, the results reported here open the route to an effective methodology to store, manipulate and process volumetric images, especially for lab-on-chip systems, which require a small memory footprint. The results demonstrated here will lead to further developments in computational microscopy for single-cell phase-contrast tomography.

The new method is based on the 3D extension of Zernike polynomials. The 3D Zernike representation is a way of describing the shape of an

object in three dimensions. It is based on a mathematical concept called spherical harmonics and is especially good at describing objects that are roughly spherical in shape. Cells in the natural environment are often shaped like spheres, so the 3D Zernike representation can be a useful tool for studying them.

The authors demonstrated that the 3D refractive index distribution of a cell can be straightforwardly encoded in one dimension by using 3D Zernike polynomials. They reconstructed a tomographic cell phantom and analyzed its performance by comparing to the most-used volumetric image compression strategies. The method was then validated on real-world single-cell tomography data.
