The Human Genome Project generated the first sequence of the human genome, revealing a kind of blueprint of human biology. Two decades

later, the field of gene regulatory networks describes a complex system where thousands of genes regulate one another to create appropriate gene expression dynamics.

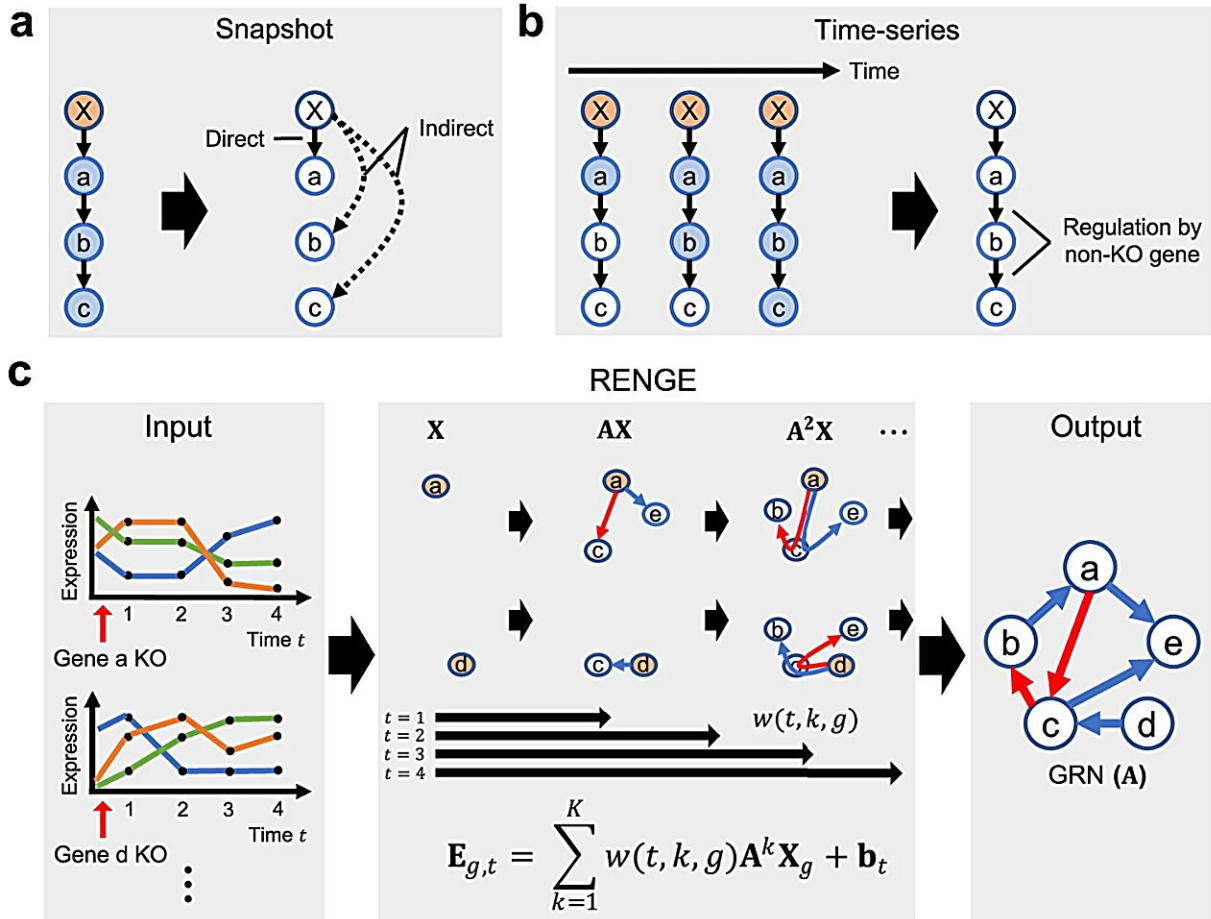

However, more work is needed to fully understand these networks and determine their precise nature. Current approaches either estimate gene regulation indirectly or utilize accurate and direct but time-consuming, repetitive methods.

A research group led by Kyoto University has now developed a highly accurate method to semi-automatically estimate gene regulatory networks in multicellular organisms. The method involves measuring time-series gene expression and applying the team's proprietary RENGE computational model. The study is [published](#) in the journal *Communications Biology*.

"RENGE may help identify the key factors for [cell differentiation](#) and potentially control the fate of specific cells," says corresponding author Masato Ishikawa of KyotoU's Institute for Life and Medical Science.

Researchers can determine regulatory gene expression using the relatively accurate gene knockout method, where if a gene A is eliminated, a gene B—that A had regulated—is exposed.

The latest single-cell CRISPR technology, which can measure expression changes from large-scale individual knockouts, comes with a caveat: The distinction between directly and indirectly regulated genes is unclear. Knocking out one gene inevitably affects the expression of genes downwind in the network.

Overview of RENGINE. a The use of snapshot expression data alone after gene X is knocked out makes it difficult to distinguish direct and indirect regulations. Blue nodes: genes with expression changes due to the KO. b Using time-series expression data after KO, in principle, can enable differentiation of direct and indirect regulations and infer regulation by non-KO genes. c RENGINE infers a signed GRN from the time-series expression data after gene KO, obtained by scCRISPR analysis, by modeling the process in which the effects of the gene KO propagate on the network. Ishikawa and his colleagues addressed the issue by measuring the [expression levels](#) in a time series and adapting their [mathematical model](#)

to estimate gene regulatory networks.

"When we verified RENGINE's accuracy, we obtained results that outperformed existing methods in both simulation data and measured expression data of human iPS cells," adds Ishikawa.

Using RENGINE to maximize information obtained from gene knockout, the team could identify a gene regulatory network containing 103 genes expressing human pluripotency, which was highly consistent with findings accumulated over decades of research in molecular biology.

"However, the beauty is that we could obtain the same results from only one RENGINE experiment. Furthermore, we found that [transcription factors](#) that regulate the same [target genes](#) in this regulatory network tend to work as protein complexes, among which one may be a key factor for pluripotency," elaborates Ishikawa.

The inherent versatility of this method allows for estimating [regulatory networks](#) in various other life systems beyond iPS cells.

"RENGE may inspire new technologies such as producing artificially manipulated cells with specific functions," remarks Ishikawa.
