The sea anemone *Nematostella vectensis* is potentially immortal. Using molecular genetic methods, developmental biologists led by Ulrich Technau from the University of Vienna have now identified possible candidates for multipotent stem cells in the sea anemone for the first time.

These stem cells are regulated by evolutionary highly conserved [genes](#), which in humans are usually only active in the formation of egg and [sperm cells](#), but give ancient animal phyla such as cnidarians a high degree of regenerative capacity to even escape aging. The results are [published](#) in *Science Advances* and could also provide insights into the human aging process in the future.

"We live as long as our stem cells" is a somewhat bold but essentially accurate statement. Stem cells contribute to the constant renewal of various cells and tissues in humans, e.g. blood cells, skin or hair. If stem cells lose this ability or their number decreases in the course of life, the body ages or develops diseases. Stem cells are therefore of great interest for biomedical research.

While humans and most vertebrates can only regenerate parts of certain organs or limbs, other animal groups have far stronger regeneration mechanisms. This ability is made possible by pluripotent or multipotent stem cells, which can form (differentiate) almost all cell types of the body.

Laser scanning microscope picture of the body of the sea anemone *Nematostella vectensis*. The red fluorescence (Nanos2) marks the transgenic putative stem cells, white (DAPI) are all cell nuclei and yellow (EdU) those cells that are actively engaged in DNA-synthesis, hence in the cell cycle like some of the stem cells. The [sea anemone](#) *Nematostella vectensis* is also highly regenerative: it can reproduce asexually by budding and also shows no signs of aging, which makes it an interesting subject for [stem cell research](#). However, researchers have not yet been able to identify any stem cells in these animals.

Using the new "Single Cell Genomics" method, Technau and his team could identify cells of a complex organism based on their specific transcriptome profiles and determine from which stem cells they have developed.

"By combining single-cell gene expression analyses and transgenesis, we have now been able to identify a large population of cells in the sea anemone that form differentiated cells such as [nerve cells](#) and glandular cells and are therefore candidates for [multipotent stem cells](#)," explains first author Andreas Denner from the University of Vienna. They have remained undiscovered until now due to their tiny size.

These potential stem cells express the evolutionarily highly conserved genes *nanos* and *piwi*, which enable the development of germ cells (sperm and egg cells) in all animals, including humans. By specifically mutating the *nanos2* gene using the CRISPR gene scissors, the scientists were also able to prove that the gene is necessary for the formation of germ cells in sea anemones. It has also been shown in other animals that this gene is essential for the production of gametes.

This proves that this gene function emerged around 600 million years ago and has been preserved to this day. In future studies, Ulrich Technau and his team now want to investigate which special properties of the sea anemone's stem cells are responsible for its potential immortality.
