

Microdroplet reactors mimic living systems

January 20 2016

Schematic diagram of chemical reactions far from equilibrium in a droplet open-reactor system controlled by pulse-density modulation. (a) In the droplet open-reactor system, the supply of substrates and the dissipation of products/wastes into/out of the reaction system are sustained, inducing self-organized phenomena based on complex chemical reaction dynamics far from equilibrium. The

chemical reactions in the droplet open-reactor system are dynamically varied based on external control and feedback control. The droplet open-reactor system is based on the repeated fusion and fission of droplets. (b) A fusion–fission process and the pulse-density modulation concept. T_j and w_j are the interval and duration of j -th fusion–fission event, respectively. $p(t; T, w)$ is a square pulse-train function used to express a fusion–fission process ($T = \{T_j\}$; $w = \{w_j\}$). q is the basal strength of the chemical fluxes. τ_j is the time at which the j -th fusion starts.

"Living systems are achieved by complex chemical reaction dynamics far from equilibrium, such as gene expression networks, signalling networks, metabolic circuits and neural networks," explains Masahiro Takinoue at Tokyo Institute of Technology. His team has demonstrated that their microdroplet system can offer the control over chemical fluxes needed to keep this kind of reaction far from equilibrium.

Takinoue and his colleagues used a microfluidic system containing a droplet of water in oil with electrodes on either side as the chemical reaction site. They then passed water in oil droplets past the reactor droplet. As each droplet passed the reactor droplet, applying an A.C. voltage across the electrodes led to fusion, allowing chemical exchange. The shear force of the droplet train then caused fission, leaving the reactor droplet self-contained until voltage-induced fusion with the following droplet.

The research team mathematically demonstrated how, by switching the A.C. voltage on and off, they could control the fusion/fission timing, and hence the chemical flux and reaction dynamics. As a model system, they then produced a microdroplet system of bromite (BrO^{3-}), sulphite (SO_3^{2-}) and ferrocyanide ($\text{Fe}(\text{CN})_6^{4-}$; /). The pH in the droplet oscillates as hydrogen cations are produced and consumed through autocatalytic reactions. Using pH-sensitive fluorescent molecules, the researchers

could monitor these reaction dynamics and incorporate feedback.

The researchers say complicated microfluidic components, such as valves and mixers, are unnecessary, as the A.C. voltage pulse-modulated reactor provides chemical flux control. In addition, the fast fusion response to the applied electric field allows the study of a range of waveforms of the droplet train density, including sinusoidal, square and saw tooth. As a result, it could provide a powerful tool for studying synthetic biology to understand life, as well as bio-inspired, self-controlling and dynamic systems.

Living far from equilibrium reactions

A system is at equilibrium when it is in its lowest free-energy state and its entropy is maximised. Many of the reactions central to the processes for life are far from equilibrium, since decomposition is the lowest energy state of the atoms and molecules in the chemicals, cellular structures and tissues that comprise living organisms.

Without control over the chemical flux, the entropy of these reactions will increase, bringing the system closer to equilibrium. In cells, this control is achieved with semipermeable membranes and highly responsive systems. In artificial systems, valves and mixers can be used, but these can be bulky and complicated. The fusion and fission of microdroplets achieves chemical flux control in a simple system that is readily scaled and extended for multiple reactors.

Droplet microfluidics

The control of small volumes of liquids—microfluidics—is a multidisciplinary field with applications in inkjet printheads, DNA chips, lab-on-a-chip technology, micro-propulsion, and micro-thermal

technologies. By using discrete [droplets](#) instead of continuous fluid flow, it is possible to digitise these systems, allowing cell-based approaches and hierarchical technologies.

Potential applications

The droplet open-reactor system may provide a complex reaction system for research in synthetic biology such as artificial DNA circuits, gene circuits, metabolic systems and microchemostat-like reactors. The researchers also suggest that the precise control over non-equilibrium chemical reactions that the system achieves will be useful for studying enzymatic networks and the production of hierarchical materials formed through biomineralization processes, such as bone.

They also say that the A.C. voltage pulse-density modulation used to control the microdroplet reactor system is compatible with control theory for dynamical systems in general. In addition, it may have applications in computational intelligence, which is a set of methods inspired by nature that are designed to tackle real-world problems intractable to traditional mathematical approaches. It is also an ideal platform for developing software-wetware technologies.
