The occurrence of emotions in animals has been under debate. Now, a research collaborative has demonstrated for the first time that fish have emotional states triggered by the way they perceive environmental stimuli. This study, published in *Scientific Reports*, reveals that the ability to assess emotional stimuli may have a simpler neurological basis than expected, which was conserved throughout animal evolution.

Tests were held in sea bream after the fish were trained under favourable or adverse conditions that could trigger an emotional state. Contrarily to what is expected in a non-emotional response, the researchers observed that fish responded differently to the same stimulus depending on the way they assessed the stimulus. The emotional reactions were monitored through the evaluation of interaction or escape behaviours among fish, measuring the levels of cortisol, a stress hormone, and assessing the brain areas that were activated and that are known to be associated with positive and negative emotional states.

"This is the first time that physiologic and neuromolecular responses have been observed in the central nervous system of fish in response to emotional stimuli based on the significance that the stimulus has for the fish," says Rui Oliveira. The researcher says, "The occurrence of the cognitive assessment of an emotional stimulus in fish means that this cognitive capacity may have 'computational' requirements simpler than what has been considered until now, and may have evolved around 375 million years ago."
