Hypoxic dead zones found in urban streams, not just at the coast
11 December 2018

A new study finds that hypoxic dead zones, where dissolved oxygen levels in water drop so low that fish and other animals suffocate, occur in urban streams such as this one in Raleigh, N.C. Credit: Duke University

Hypoxic dead zones, which occur when dissolved oxygen levels in water drop so low that fish and other aquatic animals living there suffocate, are well-documented problems in many coastal waters.

Now, a new Duke University-led study reveals they also occur in freshwater urban streams.

"We were surprised to find these dead zones are happening in our own backyards, not just in rivers and coastal waters downstream of major point sources of nutrient pollution," said study leader Joanna Blaszczak, a 2018 doctoral graduate of Duke's Nicholas School of the Environment.

Blaszczak and her colleagues published their peer-reviewed study Dec. 3 in the journal Limnology & Oceanography.

To conduct the study, they measured dissolved oxygen concentrations, light levels, water chemistry and stream flow in six streams draining urban watersheds in Durham and Raleigh, N.C., from 2015 to 2017.

They used the data to model the growth of algae and oxygen-consuming bacteria in the streams and examine the frequency at which dissolved oxygen concentrations dropped below two milligrams per liter—the danger point for fish and other aquatic organisms.

"Streams draining developed areas are subject to intense, erosive storm flows when roads and stormwater pipes rapidly route runoff into streams during storms, without allowing the water to infiltrate into the soil," Blaszczak said.

"We found that erosion caused by these intense flows changed the shape of some stream channels to such an extent that water essentially stopped flowing in them during late summer. They became a series of pools containing high levels of nutrient runoff and organic matter, including nitrogen from leaking sewer pipes, fertilizer and pet waste."

The elevated nutrient levels spurred greater consumption of dissolved oxygen by bacteria in the water, causing the pools to become hypoxic until the next storm flushed them out.

Some streams were found to be more vulnerable than others, depending on their underlying geology.

"Channels that are more susceptible to erosion can become impounded by newly exposed bedrock outcroppings and culverts, leading to the formation of the between-storm pools that are so prone to hypoxia," Blaszczak explained.

"We found that growth rates of algae that support stream food webs was slower in streams with more frequent intense storm flows. Together with the..."
occurrence of hypoxia, this paints a bleak and stressful picture for freshwater organisms that are trying to survive in these urban streams," she said.

While the study was conducted only in small streams draining urban watersheds, its findings are broadly applicable, Blaszczak noted, because pools are ubiquitous features of rivers, made even more so by the long-term legacies of dam building and dam removal.

"Hypoxia is not commonly assumed to occur in streams and rivers because of stream flow, which typically moves water fast enough to prevent the drawdown of dissolved oxygen by bacteria to hypoxic levels," she said. "However, dam building and other human alterations that stop the flow of water make these freshwater ecosystems particularly vulnerable to hypoxia with negative implications for biodiversity, especially in rivers already burdened with high nutrient pollution."
