Making the invisible visible: Entangled photons for imaging and measurement techniques
2 April 2020, by Annika Höft

Entangled photons can be used to improve imaging and measurement techniques. A team of researchers from the Fraunhofer Institute for Applied Optics and Precision Engineering IOF in Jena has developed a quantum imaging solution that can facilitate highly detailed insights into tissue samples using extreme spectral ranges and less light.

While optical analysis techniques such as microscopy and spectroscopy are extremely efficient in visible wavelength ranges, they quickly reach their limits in the infrared or terahertz range. That, however, is precisely where valuable information is hidden. For example, bio-substances such as proteins, lipids and other biochemical components can be distinguished based on their characteristic molecular vibrations. These vibrations are stimulated by light in the mid-infrared to terahertz range and are very difficult to detect with conventional measurement techniques. "If these motions could be captured or induced, it would be possible to see exactly how certain proteins, lipids and other substances are distributed in cell samples. For example, some types of cancer have a characteristic concentration or expression of certain proteins. This would mean that the disease could be detected and treated more efficiently. More precise knowledge of the distribution of bio-substances could bring major advances in drug research, as well," says quantum researcher Dr. Markus Gräfe from Fraunhofer IOF.

Entangled photons—twins yet different

Entangled photons can be used to improve imaging and measurement techniques. A team of researchers from the Fraunhofer Institute for Applied Optics and Precision Engineering IOF in Jena has developed a quantum imaging solution that can facilitate highly detailed insights into tissue samples using extreme spectral ranges and less light.

But how can information from these extreme wavelength ranges be made visible? The quantum mechanical effect of photon entanglement is helping the researchers allowing them to harness twin beams of light with different wavelengths. In an interferometric setup, a laser beam is sent through a nonlinear crystal in which it generates two entangled light beams. These two beams can have very different wavelengths depending on the crystal's properties, but they are still connected to each other due to their entanglement.

"So now, while one photon beam in the invisible infrared range is sent to the object for illumination and interaction, its twin beam in the visible spectrum is captured by a camera. Since the entangled light particles carry the same information, an image is generated even though the light that reaches the camera never interacted with the actual object," explains Gräfe. The visible twin essentially provides insight into what is happening with the invisible twin.

The same principle can also be used in the ultraviolet spectral range: UV light easily damages cells, so living samples are extremely sensitive to that light. This significantly limits the time available for investigating, for instance, cell processes that last several hours or more. Since less light and
smaller doses of radiation penetrate tissue cells
during quantum imaging, they can be observed and
analyzed at high resolution for longer periods
without destroying them.

Small assembly and tiny structures

"We are able to demonstrate that the entire
complex process can be carried out in a way that is
robust, compact and portable," says Gräfe. The
researchers are currently working to make the
system even more compact, shrinking it to the size
of a shoebox, and to further enhance its resolution.
The next step they hope to achieve is, for example,
a quantum scanning microscope. Instead of the
image being captured with a wide-field camera, it
will be scanned, similar to a laser-scanning
microscope. The researchers expect this to yield
even higher resolutions of less than one
micrometer (1 µm), enabling the examination of
structures within individual cells in even greater
detail. On average, one cell measures roughly ten
micrometers in size. In the long term, they want to
see quantum imaging integrated into existing
microscopy systems as a basic technology, thus
lowering the barriers for industry users.

The demonstrator is one of the results of the
Fraunhofer lighthouse project QUILT, which pools
the quantum optics expertise of the Fraunhofer
Institutes for Applied Optics and Precision
Engineering IOF, for Physical Measurement
Techniques IPM, for Microelectronic Circuits and
Systems IMS, for Industrial Mathematics ITWM, of
Optronics, System Technologies and Image
Exploitation IOSB and for Laser Technology ILT.
