

Using DNA-like punch cards to store data

April 15 2020, by Bob Yirka

Writing and reading the encoded data. a PfAgo can nick several pre-designated locations on only one strand (left, top) or both strands (left, bottom), simultaneously. In the first register, the stored content is 110...1, while in the second register, the content is 121...0. The chosen register is a PCR product of a 450 bp *E. coli* genomic DNA fragment with 10 pre-designated non-uniformly spaced nicking positions. The positional code 238 corresponds to the binary vector 0110000100 (right). b The MiSeq sequencing reads were aligned to the reference register to determine the positions of the nicks. The size distribution histogram (right) and coverage plots (left) are then generated based on the frequency and coverage depth of the reads. Coverage plots allow for straightforward detection of nicked and unnicked sites. In the example shown, all the ten positions were nicked, resulting in eleven aligned fragments. Credit:

A team of researchers at the University of Illinois and the University of Texas has developed a new way to use DNA as a data storage medium—by using them like punch cards. In their paper published in the journal *Nature Communications*, the group describes their approach and how well it worked when tested.

Over the past several years, it has become clear that a new kind of data [storage](#) is needed—the type that is used now will not be capable of storing the massive amounts of data likely to be generated in the future. This understanding has led scientists to look for alternatives, one of which is DNA. Prior research has shown that in theory, strands of DNA should be able to hold approximately one exabyte of data per cubic millimeter. And as a bonus, it would provide a medium capable of holding data stored on it for thousands of years. But thus far, attempts to use DNA in such a capacity have fallen far short of expectations—mainly because such strands require synthesizing, a lengthy and expensive undertaking. In this new effort, the researchers have found a way to use DNA strands as a data storage medium without the need for synthesis.

The new approach is based on old technology—[punch cards](#): cardboard cards that represented data elements with punched holes. But instead of cardboard and holes, the new approach involves taking tiny bites out of DNA strands, leaving small nicks behind that can be used to hold information.

To accomplish this feat, the researchers heated double strands of DNA until they no longer spiraled. Doing so also led to bubble formation forcing the bases in the strands to be exposed. Then, the researchers

applied single strands of DNA in 16 base lengths, which clung to the double strands. The ends of the single strands served as guides for enzymes, which cut notches by severing ties between nucleotides in the backbone rails of the original double strand. The end result was a series of notches cut into the backbone of a strand of DNA that could be used to hold data.

To test their idea, the researchers encoded parts of the Gettysburg address onto *Escherichia coli* DNA, and then read it back again using commercial sequencing techniques. They suggest that thus far, their approach holds great promise for resolving data storage problems of the future.
