Elusive protein complex could hold the key to treating chromosomal disorders
17 March 2021

One of the most vital functions performed by the cells in our body is DNA repair, a task so crucial to our well-being that failing to execute it can lead to consequences as dreadful as cancer. The process of DNA repair involves a complex interplay between several gene pathways and proteins. One such pathway is the "Fanconi anemia (FA) pathway," whose genes participate in DNA repair. FANCM, a component of this pathway, is tasked with the elimination of harmful DNA "inter-strand cross-links," and interacts with another component called MHF in order to function. FANCM-MHF complex is well-documented: its loss can result in chromosomal instabilities that can lead to diseases such as FA itself and cancer. However, little is known about its structure and the basis of its stability.

Against this backdrop, Associate Professor Tatsuya Nishino and his colleague Dr. Sho Ito from Tokyo University of Science decided to explore the crystalline structure of this intriguing complex using X-ray diffraction techniques. "DNA damage and chromosome segregation are mechanisms necessary for the maintenance and inheritance of genes possessed by all organisms. MHF (also known as CENP-SX) is an enigmatic complex that plays a role in DNA repair and chromosome segregation. We wanted to find out how it performs these two different functions in the hope that it might give us insights into novel phenomena," explains Prof. Nishino. Their findings are published in Acta Crystallographica Section F: Structural Biology Communications.

The scientists prepared a recombinant version of the FANCM-MHF complex, consisting of FANCM from chickens and MHF1 and MHF2. They were able to purify three different types of protein crystals—tetrahedral, needle-shaped, and rod-shaped—from similar crystallization conditions. Surprisingly, upon determining the structure with X-ray crystallography, they found that two of the crystal forms (tetrahedral and needle-shaped) contained only the MHF complex without FANCM.

Intrigued by this discovery, the scientists used biochemical techniques to examine what caused the FANCM-MHF complex to disassemble. They attributed it to the presence of a compound called 2-methyl-2, 4-pentanediol (MPD), an organic solvent commonly used in crystallography, and exposure to an oxidizing environment.

But, how exactly does the dissociation happen? The scientists believe that this may have been caused partly by certain non-conserved amino acids in the chicken FANCM which causes the complex to aggregate with other FANCM-MHF complexes and disassemble. Additionally, they surmise that the small, flexible structure of MPD may have also allowed it to bind to and facilitate the release of FANCM, dismantling the complex.

The findings are extraordinary and can be used to improve the stability of the FANCM-MHF complex.
for future studies on its structure and function. Dr. Ito believes we have much to expect in the future from this complex. "A good understanding of this complex can help us treat cancer and genetic diseases, create artificial chromosomes, and even develop new biotechnological tools," he speculates.

Thanks to Prof. Nishino and Dr. Ito's efforts, we are already one step closer to that goal.
